Abstract

We study a multiple relaxation time lattice Boltzmann model for natural convection with moment–based boundary conditions. The unknown primary variables of the algorithm at a boundary are found by imposing conditions directly upon hydrodynamic moments, which are then translated into conditions for the discrete velocity distribution functions. The method is formulated so that it is consistent with the second–order implementation of the discrete velocity Boltzmann equations for fluid flow and temperature. Natural convection in square cavities is studied for Rayleigh numbers ranging from $10^3$ to $10^6$. An excellent agreement with benchmark data is observed and the flow fields are shown to converge with second order accuracy.

1. Introduction

Natural convection occurs in a diverse range of phenomena, from thermal flows in the atmosphere [1] to small scale microfluidics [2]. Its significance has generated much interest in the scientific and engineering communities, including computational fluid dynamics (CFD) (see, for example, [3, 4, 5, 6, 7, 8]). The classic benchmark test for numerical methods is thermal flow in a square cavity comprised of two adiabatic horizontal walls (i.e., Neumann boundary conditions) and two thermally fixed vertical walls (i.e., Dirichlet boundary conditions), where the left wall is hotter than the right. This flow is dictated by two non–dimensional numbers, namely the Prandtl number, \( Pr \), and Rayleigh number, \( Ra \). The Prandtl number is the ratio of momentum to thermal diffusivity; the value \( Pr = 0.71 \) is generally taken for air, and \( Pr = 7 \) represents water near temperature. The onset of convection is determined by the critical Raleigh number and its magnitude indicates whether the convection boundary layer is laminar or turbulent (\( Ra \gtrsim 10^6 \) for turbulent flows).

Traditional algorithms involve a direct discretisation of the highly non–linear partial differential equations of continuum fluid mechanics, namely the Navier–Stokes equations with a Boussinesq approximation for the buoyancy. An alternative to the more familiar methods of CFD is the lattice Boltzmann equation (LBE), which is based on a velocity–space truncation of the Boltzmann equation of classical kinetic theory [9]. By seeking solutions which vary slowly over hydrodynamic timescales much longer than the collision time, \( \tau_\nu \), the (lattice) Boltzmann equation can be shown to approximate the Navier–Stokes equations [10, 11, 12]. This seemingly indirect method offers several computational advantages. The non–linear convection term in the
macroscopic equations is replaced by linear, constant coefficient advection in the discrete velocity Boltzmann equation. Furthermore, all non-linearities are confined to an algebraic source term which can be updated locally, grid-point by grid-point. The simplicity and locality of the algorithm allow for an extension to flows in highly irregular geometries and a natural parallelisation on modern computer architectures [13, 14, 15].

The application of the lattice Boltzmann model to thermal flows began two decades ago [16, 17, 18]. Alexander et al. [16] adopted a multi-speed approach to study Couette flow with an imposed temperature gradient and Bartoloni et al. [17] studied Rayleigh-Bénard convection by modelling the temperature as a passive scalar. To improve the numerical stability of thermal lattice Boltzmann models, McNamara et al. [19] used a Lax–Wendroff scheme to discretise the advection term. This method introduces greater artificial viscosity and the authors concluded that their method offered no advantages over finite difference methods.

Shan [20] studied Rayleigh-Bénard convection using a lattice Boltzmann model with two distribution functions, one for the fluid flow and another for the thermal transport. By comparing their simulation results with those of Clever and Busse [8], the authors concluded that the steady-state Nusselt numbers were in good agreement for $Ra < 20000$, but deviated at higher values. He et al. [21] evolved the temperature by an internal energy distribution function, rather than a passive-scalar approach. Similar to the model of Shan [20], this method was able to make predictions in good agreement with Clever and Busse’s [8] benchmark simulations for $Ra < 20000$ but gave quantitatively incorrect results at higher Rayleigh numbers.
Dixit et al. [22] combines the ‘double-population’ approach of He et al. [21] with both an interpolation-supplemented method [23] and an extension to Inamuro’s counter-slip technique [24] to accurately incorporate the boundary conditions. Laminar flow simulations were compared to the benchmark solution of de Vahl Davis [3] and an agreement within 3% noticed. Turbulent flow simulations at Rayleigh numbers between $10^7$ and $10^{10}$ were within a 5% agreement when compared to Le Quere [6] and Markatos et al. [4]. The authors credited their model’s accuracy to the fine grid resolution at the wall boundary. One would expect, however, a robust numerical method to be able to produce reliable results for the this flow without the need for excessive refinements or expensive interpolation between points.

The models of Guo et al. [25, 26] consist of two independent LBEs (one for hydrodynamics, one for the temperature) on separate lattices which are coupled together through a term added to the fluid distribution function. Li et al. [27] present a coupled lattice Boltzmann model for thermal flows based on the double-distribution function of Guo et al. [26] using for both the BGK and MRT collision schemes. Their results show that the MRT collision operator offers greater numerically stability than the BGK scheme. Hybrid thermal lattice Boltzmann models have been proposed or studied by Lallemand et al. [28], Mezrhab et al. [29], and Choi and Kim [30]. Lallemand et al. argued that previous thermal lattice Boltzmann models were based on a spurious coupling between the viscous and energy modes. To circumvent this, they evolved the hydrodynamics using an LBE and the temperature field using a finite difference algorithm.

Wang et al. [31] present a thermal lattice Boltzmann model with multiple
relaxation times for both the fluid and transport equations. The anti-bounce-back method to implement Dirichlet boundary conditions and bounce-back for the Neumann boundary conditions. The authors compare their results with several other methods in the literature [3, 5, 6, 25, 29] and provide the most detailed study of a lattice Boltzmann model for natural convection to date. By computing the $L_2$ error norm for the flow fields (velocity, pressure, and temperature) Wang et al. show their algorithm converges with second-order in space. The computed Nusselt numbers are in good agreement with benchmark solutions for a range of Rayleigh numbers and the authors emphasise the importance of using multiple relaxation.

Part of the motivation for using multiple relaxation times in [31] is to eliminate the numerical slip error that plagues the bounce–back method [32, 33]. That is, the collision time for the third order moment is chosen so that, as accurately as possible, $u = 0$ at the walls. This places an additional restriction on the collision operator. Ideally one would choose the relaxation times purely on the ground of numerical stability and not according to the boundary conditions. In particular, the value of the collision time for the third order moment needed to minimise the numerical slip error is not necessarily optimal [34].

Similar in spirit to the original work of Noble et al. [35], Bennett [36] proposed a general methodology for implementing lattice Boltzmann boundary conditions in terms of the moments of the distribution functions. Unlike bounce-back and its variants, this ‘moment method’ assumes a wall to be located precisely at grid points. The method remains fully local and does not require any additional finite difference approximations nor any interpo-
ation/extrapolation of quantities to or from neighbouring nodes. The drawback of the approach is evident: a lack of flexibility for flows in complicated geometries. It does, however, guarantee the satisfaction of hydrodynamic quantities at the boundaries, allowing for greater freedom in the choice of relaxation times. It is thus natural to inquire if the moment method can be applied to natural convection and, if so, to assess its accuracy.

It is article we develop lattice Boltzmann boundary conditions for natural convection in the framework of the moment method. We use a second order in time discretisation [37] of two discrete-velocity Boltzmann equations, one for the fluid flow and one for the thermal transport, coupled through a force term for the buoyancy (Boussinesq approximation). A multiple relaxation time collision operator is used for each, where the collision time for the third order moment of the fluid LBE is chosen according to numerical stability and the collision times for the thermal transport chosen so that the numerical diffusion is isotropic to fourth order. The boundary conditions are imposed on the moments of each distribution function, and then translated into conditions for the primary variables of the algorithm. Our implementation does not lose the computational advantages of the lattice Boltzmann method and inherits its second order accuracy. The proposed model is assessed with the classic benchmark test of convection in a square cavity for Rayleigh numbers ranging from $10^3$ to $10^6$. It is also shown how the moment method can be applied to the industrially-relevant problem of convection in partially open geometries.

The remainder of the article is organised as follows. Section 2 introduces the governing macroscopic equation of motion and Section 3 presents...
the lattice Boltzmann formulation of the problem. Section 4 develops the moment–based boundary conditions, and the multiple relaxation time extension is discussed in Section 5. Numerical simulations of convection in a square cavity and a partially heated cavity are presented in Sections 6 and 7, respectively, with concluding remarks left to Section 8.

2. Governing macroscopic equations

Natural convection is a buoyancy-driven flow which can be modelled with the Boussinesq approximation. This approximation assumes that density variations due to temperature can be neglected in all but the gravity acceleration term, which is included as a body force in the Navier–Stokes equations,

\[ \rho \left[ \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right] = -\nabla P + \mu \nabla^2 \mathbf{u} + \mathbf{F}, \]  
\[ \nabla \cdot \mathbf{u} = 0, \]  
where \( \rho \) is the density, \( \mathbf{u} \) is the flow velocity, \( P \) is pressure, \( \mu \) is the dynamic viscosity, and \( \mathbf{F} \) is the body force acting on the fluid. This force is given by \( \mathbf{F} = \rho \alpha (\phi - \phi_0) \mathbf{g} \), where \( \alpha \) is the thermal expansion coefficient, \( \phi \) and \( \phi_0 \) are the temperature and reference temperature, respectively, and \( \mathbf{g} = (0, g) \) is the gravitational acceleration. The temperature evolves according to the advection–diffusion equation,

\[ \frac{\partial \phi}{\partial t} + \mathbf{u} \cdot \nabla \phi = D \nabla^2 \phi, \]  
where \( D \) is the thermal diffusion coefficient.
Equations (1)–(3) are non-dimensionalised by scaling

\[ t' = t \frac{D}{L^2}, \quad x' = \frac{x}{L}, \quad u' = \frac{uL}{D}, \quad P' = P \frac{L^2}{\rho_0 D^2}, \quad \]

\[ \theta := \frac{(\phi - \phi_0)}{\Delta \phi}, \]

where \( \Delta \phi \) is the temperature difference (between the hot and cold walls in this study). Defining the Prandtl and Rayleigh numbers to be

\[ Pr = \frac{\nu}{D}, \quad Ra = \frac{\alpha g (\phi - \phi_0) L^3}{\nu D}, \]

allows us to write the governing equations in non-dimensional form:

\[ \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla P + Pr \nabla^2 \mathbf{u} + Ra Pr \theta \hat{g}; \]

\[ \nabla \cdot \mathbf{u} = 0; \]

\[ \frac{\partial \theta}{\partial t} + \mathbf{u} \cdot \nabla \theta = \nabla^2 \theta, \]

where \( \hat{g} \) is a unit vector in the vertical direction and we have omitted primes for clarity. The kinematic viscosity, \( \nu \), and the diffusion coefficient, \( D \), are given in terms of the non-dimensional numbers:

\[ \nu = \sqrt{\frac{\alpha g \Delta \phi L^3 Pr}{Ra}}; \quad D = \sqrt{\frac{\alpha g \Delta \phi L^3}{Pr Ra}}. \]

The characteristic velocity of the flow is

\[ U = \sqrt{\alpha g \Delta \phi L}. \]

The flow physics in natural convection are controlled by \( Pr \) and \( Ra \). Small Prandtl number flows, such as for air \((Pr = 0.71)\), are dominated by thermal diffusion, while large Prandtl numbers \((Pr = 7 \text{ for water near room temperature})\) correspond to momentum diffusion dominated flows. The
onset of convection is governed by the Rayleigh number, where beyond some critical value the flow exhibits a Rayleigh–Bénard instability and the primary form of thermal transport changes from conduction to convection.

3. The discrete Boltzmann formulation

We postulate two discrete–velocity Boltzmann equations (DBEs), one to describe the evolution of the fluid flow \( f_i \) and another for thermal transport \( g_i \):

\[
\frac{\partial f_i}{\partial t} + c_i \cdot \nabla f_i = -\frac{1}{\tau_\nu} \left( f_i - f_i^{(eq)} \right) + R_i, \quad (12)
\]

\[
\frac{\partial g_i}{\partial t} + c_i \cdot \nabla g_i = -\frac{1}{\tau_D} \left( g_i - g_i^{(eq)} \right), \quad (13)
\]

where \( \tau_\nu \) and \( \tau_D \) are the relaxation times associated with viscous and thermal diffusion, respectively, and \( R_i \) is the forcing term. The discrete particle velocity set \( \{ c_i \} \) for \( f_i \) is the D2Q9 lattice shown in Figure 1, while that for the (linear) advection–diffusion equation is the D2Q5 lattice model \( (i = 0, \ldots, 4) \). The equilibrium functions \( f_i^{(eq)} \) and \( g_i^{(eq)} \) are given by

\[
f_i^{(eq)} = W_i \rho \left[ 1 + 3c_i \cdot u + \frac{9}{2} (c_i \cdot u)^2 - \frac{3}{2} u^2 \right], \quad (14)
\]

\[
g_i^{(eq)} = T_i \phi [1 + 3c_i \cdot u], \quad (15)
\]

where the weights \( W_0 = 4/9, W_i = 1/9 \) for \( i = 1, \ldots, 4 \), \( W_i = 1/36 \) for \( i = 5, \ldots, 8 \), and \( T_0 = 1/3, T_i = 1/6, i = 1, \ldots, 4 \).

The source term \( R_i \) introduces the body force \( \mathbf{F} \) and must satisfy

\[
\sum_i R_i = 0, \quad \sum_i R_i c_i = \mathbf{F}, \quad \sum_i R_i c_i c_i = \mathbf{F} u + u \mathbf{F}. \quad (16)
\]
The first constraint in (16) is a statement of mass conservation and the second accounts for the buoyancy effect. The third condition ensures $\mathbf{F}$ does not appear in the viscous stress term in the Navier–Stokes equations (27). The explicit form of $R_i$ is [38]

$$\begin{align*}
R_i &= W_i \left[ 3 (\mathbf{c}_i - \mathbf{u}) + \frac{9\mathbf{c}_i \cdot \mathbf{u}}{2} \mathbf{c}_i \right] \cdot \mathbf{F}.
\end{align*}$$

(17)

The hydrodynamic quantities, namely fluid density ($\rho$), momentum ($\rho \mathbf{u}$), momentum flux ($\mathbf{\Pi}$), thermal density ($\phi$), and thermal flux ($\Psi$) are defined by moments of the distribution functions:

$$\begin{align*}
\rho &= \sum_{i=0}^{8} f_i; \quad \rho \mathbf{u} = \sum_{i=0}^{8} f_i \mathbf{c}_i; \quad \mathbf{\Pi} = \sum_{i=0}^{8} f_i \mathbf{c}_i \mathbf{c}_i; \\
\phi &= \sum_{i=0}^{4} g_i; \quad \Psi = \sum_{i=0}^{4} g_i \mathbf{c}_i.
\end{align*}$$

(18)
Taking the 0th-, 1st-, and 2nd-order moments of equation (12) yields

\[
\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{u} = 0, \quad (20)
\]
\[
\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot \mathbf{\Pi} = \mathbf{F}, \quad (21)
\]
\[
\frac{\partial \mathbf{\Pi}}{\partial t} + \nabla \cdot \mathbf{Q} = -\frac{1}{\tau_\nu} (\mathbf{\Pi} - \mathbf{\Pi}^{(eq)}), \quad (22)
\]

Equations (20) and (21) are the conservation laws for mass and momentum (with a body force). The momentum flux, \( \mathbf{\Pi} \), is not conserved by collisions and relaxes to equilibrium \( \mathbf{\Pi}^{(eq)} = \sum_i f_i^{(eq)} c_i c_i \) according to its own partial differential equation (22). The third order moment in equation (22) is given by \( \mathbf{Q} = \sum_i f_i c_i c_i c_i \).

The Navier–Stokes equations can be obtained from the discrete Boltzmann equation (12) by looking for solutions that vary slowly over timescales much longer than the collision time \( \tau_\nu \) [10]. Using the Chapman-Enskog expansion,

\[
\frac{\partial}{\partial t} = \frac{\partial}{\partial t_0} + \tau_\nu \frac{\partial}{\partial t_1} + ..., \quad (23)
\]
\[
\mathbf{\Pi} = \mathbf{\Pi}^{(0)} + \tau_\nu \mathbf{\Pi}^{(1)} + ..., \quad (24)
\]
\[
\mathbf{Q} = \mathbf{Q}^{(0)} + \tau_\nu \mathbf{Q}^{(1)} + ..., \quad (25)
\]

we find the (weakly compressible) Navier–Stokes equations to leading order,

\[
\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{u} = 0, \quad (26)
\]
\[
\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot \left( \mathbf{\Pi}^{(0)} + \tau_\nu \mathbf{\Pi}^{(1)} \right) = 0, \quad (27)
\]

where

\[
\mathbf{\Pi}^{(0)} = \mathbf{P} \mathbf{I} + \rho \mathbf{uu}, \quad \mathbf{\Pi}^{(1)} = -\frac{1}{3} \rho \left( \nabla \mathbf{u} + (\nabla \mathbf{u})^T \right) + \mathcal{O}(Ma^3). \quad (28)
\]
The kinematic viscosity is seen to be a function of the relaxation time, \( \nu = \tau_\nu/3 \), and the pressure is given by an ideal equation of state, \( P = \rho/3 \).

A similar procedure applied to the discrete Boltzmann equation (13) for \( g_i \) with the expansion \( \Psi = \Psi^{(eq)} + \tau_D \Psi^{(1)} + \ldots \), yields at leading order the convection–diffusion equation

\[
\frac{\partial \phi}{\partial t} + \nabla \cdot (\phi \mathbf{u}) = D \nabla^2 \phi - \tau_D \frac{\partial}{\partial t} \nabla (\phi \mathbf{u}) + \mathcal{O}(Ma^3),
\]

(29)

where the diffusion coefficient is given by \( D = \tau_D/3 \). The last term on the right hand side of equation (29) (which is \( \mathcal{O}(Ma^2) \), where \( Ma = |u|/\sqrt{3} \) in these units) gives rise to a numerical (artificial) diffusion term which should ideally be eliminated or minimised. This will be addressed in Section 5.

3.1. The lattice Boltzmann equations

Content that the discrete-velocity Boltzmann equations (12) and (13) furnish the governing equations in the macroscopic and incompressible limit, we proceed to discretise the model in space and time. To simplify the procedure we define new equilibria

\[
f_i^{(0)} = f_i^{(eq)} + \tau_\nu R_i,
\]

(30)

so that the discrete Boltzmann equation (12) can be written as

\[
\frac{\partial f_i}{\partial t} + c_i \cdot \nabla f_i = -\frac{1}{\tau_\nu} \left( f_i - f_i^{(0)} \right).
\]

(31)

Integrating equation (31) along a characteristic for time yields

\[
f_i(x + c_i \Delta t, t + \Delta t) - f_i(x, t) = \int_0^{\Delta t} \Omega_i(x + c_is, t + s)ds,
\]

(32)
where $\Omega_i$ represents the collision term on the right hand side of equation (31). It should be noted that the left hand side of equation (32) is exact. The right hand side can be approximated using the Trapezium rule, which yields a second order accurate but implicit system of algebraic equations:

$$
   f_i(x + c_i \Delta t, t + \Delta t) - f_i(x, t) = \frac{\Delta t}{2} \left( \Omega_i(x + c_i \Delta t, t + \Delta t) - \Omega_i(x, t) \right) + O(\Delta t^3).
$$

(33)

Following He et al. [37], we introduce the new variables

$$
   \bar{f}_i(x, t) = f_i(x, t) + \frac{\Delta t}{2 \tau_v} \left( f_i(x, t) - f_i^{(0)}(x, t) \right).
$$

(34)

The previous implicit scheme (33) can now be expressed as explicit formulae for the new variables, $\bar{f}_i$, at the new timestep:

$$
   \bar{f}_i(x + c_i \Delta t, t + \Delta t) - \bar{f}_i(x, t) = -\frac{\Delta t}{\tau_v + \Delta t/2} \left( \bar{f}_i(x, t) - f_i^{(0)}(x, t) \right).
$$

We thus discard the $f_i$ and instead evolve the $\bar{f}_i$ using (35). The hydrodynamic moments must be obtained from moments of $\bar{f}_i$. The equilibrium function (14) depends on moments of $f_i$, not $\bar{f}_i$. Density is conserved and unaffected by the source term, $R_i$, and can thus be obtained just as easily from $\bar{f}_i$ as it can from $f_i$: $\rho = \sum_i f_i = \sum_i \bar{f}_i$. The velocity, $\mathbf{u}$, however, must be reconstructed from the first-order moment of $\bar{f}_i$:

$$
   \rho \mathbf{u} = \sum_i \bar{f}_i = \rho \mathbf{u} - \frac{\Delta t}{2} \mathbf{F}.
$$

(35)

The same method of discretisation applied to equation (13) yields the lattice Boltzmann equation for $\bar{g}_i$,

$$
   \bar{g}_i(x + c_i \Delta t, t + \Delta t) - \bar{g}_i(x, t) = -\frac{\Delta t}{\tau_D + \Delta t/2} \left( \bar{g}_i(x, t) - g_i^{(eq)}(x, t) \right).
$$

13
where
\[
\bar{g}_i(x, t) = g_i(x, t) + \frac{\Delta t}{2\tau_D} \left( g_i(x, t) - g_i^{eq}(x, t) \right).
\] (36)

4. Boundary conditions

We consider solid boundaries to be located precisely at grid points. Each boundary lattice node must supply incoming distribution functions to the flow domain. For example, a horizontal wall located at the top row of the computational domain has three incoming (unknown) fluid distribution functions, \( f_4, f_7, \) and \( f_8 \), and just one unknown temperature distribution function, \( \bar{g}_4 \). All other distribution functions at the boundary are known from the algorithms (35) and (36). To solve for the unknowns we need an equal number of linearly independent equations.

The moment-based method of Bennett [36] is an extension and generalisation of the method of Noble et al. [35] which formulates the boundary conditions in terms of the moments of the distribution functions, rather than on the distribution functions directly. Natural convection in a cavity (Figure 2) requires two types of boundary conditions, Dirichlet and Neumann. The solid boundaries are impermeable, rigid and stationary, and subjected to the no–slip condition. The combinations of the unknown \( \bar{f}_i \) that appear in each of the moments at horizontal and vertical walls are shown in Table 1 and Table 2, respectively, where \( \bar{S}_{xxyy} = \sum_i \bar{f}_i c_{ix}^2 c_{iy}^2 \). Our three linearly independent equations are obtained by choosing three moments, one from each row of the appropriate table, and imposing boundary conditions upon these moments. The three equations can then be solved for the three unknowns in terms of the moment constraints and the known distributions. Since we
Moments | Combination of unknowns at South boundary | Combination of unknowns at North boundary
---|---|---
ρ, ρ̅u_y, ̃Π_yy | ̅f_2 + ̅f_5 + ̅f_6 | ̅f_4 + ̅f_7 + ̅f_8
ρ̅u_x, ̃Π_xx, ̃Q_xyy | ̅f_5 - ̅f_6 | ̅f_7 - ̅f_8
̃Π_xx, ̃Q_xyy, ̃S_xxyy | ̅f_5 + ̅f_6 | ̅f_7 + ̅f_8

Table 1: Moment groups for a south and north boundary

Moments | Combination of unknowns at East boundary | Combination of unknowns at West boundary
---|---|---
ρ, ρ̅u_x, ̃Π_xx | ̅f_3 + ̅f_6 + ̅f_7 | ̅f_1 + ̅f_5 + ̅f_8
ρ̅u_y, ̃Π_xy, ̃Q_xxy | ̅f_6 - ̅f_7 | ̅f_5 - ̅f_8
̃Π_yy, ̃Q_xyy, ̃S_xxyy | ̅f_6 + ̅f_7 | ̅f_5 + ̅f_8

Table 2: Moment groups for an east and west boundary

are computing the Navier–Stokes equations, it is logical to choose the hydrodynamic moments: the two components of momentum and the remaining independent component of the momentum flux. The no-slip and no-flow boundary conditions state \( u_x = u_y = 0 \), and require the tangential derivative of the tangential component of velocity to vanish at a solid boundary, \( \partial_T u_T = 0 \), where \( T \) denotes the tangential component. By equations (24) and (28), and remembering that \( u_T = 0 \), this third condition can be expressed as \( \Pi_{TT} = \Pi_{TT}^{(0)} = \rho/3 \). It is now simple to solve the resulting equations for the three incoming distribution functions.

It is important to respect the variable transformation (34). That is, we
place conditions on the flow variables, which must then be expressed in terms of "barred" quantities. For a concrete example, let’s consider a southern boundary. Using the above system of equations and constraints, we can compute the unknown $\bar{f}_i$ at a south wall by

$$\bar{f}_2 = \bar{f}_1 + \bar{f}_3 + \bar{f}_4 + 2(\bar{f}_7 + \bar{f}_8) - \frac{\rho}{3} - \frac{\Delta t}{2} \rho F_y,$$  \hfill (37)

$$\bar{f}_5 = -\bar{f}_1 + \bar{f}_8 + \frac{\rho}{6},$$  \hfill (38)

$$\bar{f}_6 = -\bar{f}_3 + \bar{f}_7 + \frac{\rho}{6}. \hfill (39)$$

The density, $\rho$, at the wall can be found in terms of the imposed velocity and the known distribution functions:

$$\rho = \rho \bar{u}_y + \bar{f}_0 + \bar{f}_1 + \bar{f}_3 + 2(\bar{f}_4 + \bar{f}_7 + \bar{f}_8),$$ \hfill (40)

$$\rho = -\rho \frac{\Delta t}{2} F_y + \bar{f}_0 + \bar{f}_1 + \bar{f}_3 + 2(\bar{f}_4 + \bar{f}_7 + \bar{f}_8),$$ \hfill (41)

$$\rho = \frac{2 (\bar{f}_0 + \bar{f}_1 + \bar{f}_3 + 2(\bar{f}_4 + \bar{f}_7 + \bar{f}_8))}{2 + \Delta t F_y}. \hfill (42)$$

Special attention must be paid to the corners, where there are five unknown $\bar{f}_i$. We simultaneously apply the conditions placed on the vertical and horizontal walls to give constraints on $\rho u_x$, $\rho u_y$, $\Pi_{xx}$ and $\Pi_{yy}$. The fifth constraint is $\Pi_{xy} = 0$, which eliminates the shear stress. As an example, the
incoming functions at a south-west corner in a cavity are

\[ \bar{f}_1 = \frac{2\rho}{3} - \bar{f}_0 - \bar{f}_3 - \frac{\Delta t}{2} \rho F_y, \]
\[ \bar{f}_2 = \frac{2\rho}{3} - \bar{f}_0 - \bar{f}_4, \]
\[ \bar{f}_5 = -\frac{2\rho}{3} + \bar{f}_0 + \bar{f}_3 + \bar{f}_4 + \bar{f}_7 + \frac{\Delta t}{4} F_y, \]
\[ \bar{f}_6 = \frac{\rho}{6} - \bar{f}_3 - \bar{f}_7, \]
\[ \bar{f}_8 = \frac{\rho}{6} - \bar{f}_4 - \bar{f}_7 + \frac{\Delta t}{4} F_y, \]

where \( \rho = 2 \left( 4\bar{f}_7 + 2\bar{f}_3 + 2\bar{f}_4 + \bar{f}_0 \right) / (2 + \Delta t F_y) \).

The lattice Boltzmann equation for the thermal flow must supply one incoming \( \bar{g}_i \) at the boundaries. For the heated walls the Dirichlet boundary condition can be realised by solving \( \phi_{\text{wall}} = \sum_i g_i = \sum_i \bar{g}_i \) for the incoming \( \bar{g}_i \).

The Neumann boundary condition for the adiabatic walls require \( \mathbf{n} \cdot \nabla \phi = 0 \), where \( \mathbf{n} \) is the unit vector normal to the wall. Since the temperature flux is found from the non–equilibrium part of \( g_i \), and remembering that \( \mathbf{u} = 0 \), our one constraint is chosen to be \( \Psi_N = \sum_i g_i c_{iN} = 0 \), where \( c_{iN} \) is the normal component of the particle velocity. This reduces to simple ‘bounce-back” for \( \bar{g}_i \), and once we have found the incoming \( \bar{g}_i \) we can compute the wall temperature needed for the force term in the boundary conditions for \( \bar{f}_i \). We must supply two unknown \( \bar{g}_i \) at the corners of the cavity, and these are found by applying the conditions on the vertical and horizontal walls simultaneously.

We note again that this method does not require constraints to be placed on the collision operator in order to satisfy hydrodynamic boundary conditions.
5. Multiple relaxation times

To improve accuracy and numerical stability one should use a multiple relaxation time (MRT) collision operator [39, 40, 41, 34]. The construction of the MRT scheme for $\tilde{f}_i$ presented here follows closely the model of Dellar [42], which forms an orthogonal basis in $\mathbb{R}^9$ by introducing the ghost moments

$$\bar{J} = \sum_{i=1}^{8} H_i \bar{f}_i c_i, \quad \bar{N} = \sum_{i=1}^{8} H_i \bar{f}_i,$$

(48)

where $H_i = (1, -2, -2, -2, -2, 4, 4, 4, 4)^T$. The velocity distribution function $\tilde{f}_i$ can now be expressed in terms of the nine independent moments

$$\tilde{f}_i = W_i \left( \rho + 3 \rho u \cdot c_i + \frac{9}{2} \left( \bar{\Pi} - \frac{\rho}{3} \mathbf{1} \right) : \left( c_i c_i - \frac{1}{3} \mathbf{1} \right) \right) + W_i H_i \left( \frac{1}{4} \bar{N} + \frac{3}{8} c_i \cdot \bar{J} \right).$$

(49)

The equilibrium ghost moments are $N^{(0)} = J^{(0)} = 0$.

Each non–conserved moment is relaxed to equilibrium with its own collision time. In particular,

$$\bar{\Pi}^\prime = \bar{\Pi} - \frac{\Delta t}{\tau_{\nu} + \Delta t/2} \left( \bar{\Pi} - \Pi^{(0)} \right),$$

(50)

$$\bar{J}^\prime = \bar{J} - \frac{\Delta t}{\tau_{J} + \Delta t/2} \left( \bar{J} - J^{(0)} \right),$$

(51)

$$\bar{N}^\prime = \bar{N} - \frac{\Delta t}{\tau_{N} + \Delta t/2} \left( \bar{N} - N^{(0)} \right),$$

(52)

where the primes denote post-collisional moments. The general MRT algorithm with moment–based boundary conditions is summarised as follows:

1. construct the moments of $\tilde{f}_i$;
2. construct the equilibrium moments (remembering equation (30));
3. relax the non-conserved moments according to equations (50)–(52);
4. reconstruct the distribution function (49) using the post-collisional moments;
5. advect;
6. apply boundary conditions.

The moment-based boundary conditions discussed in Section 4 are free from numerical slip and allow us to choose the relaxation times for the ghost moments purely on the grounds of numerical stability. The numerical properties of the lattice Boltzmann algorithm are primarily controlled not by each individual relaxation time but by the product $\Lambda = \tau_\nu \tau_J$ [34]. One should determine $\tau_\nu$ according to the non-dimensional numbers that characterise the flow (here the Rayleigh and Prandtl numbers) and fix $\tau_J$ according to $\Lambda$. The value $\Lambda = 1/4$ eliminates the recurrence of the non-equilibrium parts of the moments and gives the optimal stability [34]. Throughout this article we use $\Lambda = 1/4$ and $\tau_N = \tau_\nu$ (that is, a two-relaxation-time model).

The multiple relaxation time model for $\bar{g}_i$ is designed to minimise the numerical diffusion term in equation (29). We use the same model as Wang et al. [31] (but in terms of $\bar{g}_i$) which constructs the moments

\[
\begin{bmatrix}
\phi \\
\bar{g}_{ux} \\
\bar{g}_{uy} \\
\bar{K}_{xx} \\
\bar{K}_{yy}
\end{bmatrix} =
\begin{bmatrix}
1 & 1 & 1 & 1 \\
0 & 1 & 0 & 1 \\
0 & 0 & 1 & 0 \\
-4 & 1 & 1 & 1 \\
0 & 1 & -1 & 1 & -1
\end{bmatrix}
\begin{bmatrix}
\bar{g}_0 \\
\bar{g}_1 \\
\bar{g}_2 \\
\bar{g}_3 \\
\bar{g}_4
\end{bmatrix}
\] (54)
with equilibria

\[
\begin{bmatrix}
\phi, \; \phi u_x, \; \phi u_y, \; A\phi, \; 0
\end{bmatrix}.
\]

(55)

A Chapman–Enskog analysis shows that the diffusion coefficient is now a function of the parameter \( A \) as well as the relaxation time for the temperature flux, \( D = \tau_D(4 + A)/10 \). Furthermore, to ensure that the numerical diffusion term is isotropic at fourth order, one should fix \( \tau_D = \sqrt{3}/6 \) and adjust \( A \) according to the Rayleigh and Prandtl numbers. The relaxation times for the ghost moments are \( \tau_K = \sqrt{3}/3 \) [31].

6. Natural convection in a square cavity

We study the benchmark problem of convection in a unit square cavity, as illustrated in Figure 2. The side walls have a fixed temperature and the top and bottom walls are insulated. All the walls are impermeable to fluid flow and are rigid, thus the no-slip boundary condition applies. To assess the accuracy of the proposed model we compute the volume averaged Nusselt number, the average Nusselt number along the hot wall, and the average Nusselt along the centreline, which are defined to be

\[
Nu = \int_x \int_y q_x \, dy \, dx, \quad Nu_0 = \int_y q_x \, dy \big|_{x=0}, \quad Nu_{1/2} = \int_y q_x \, dy \big|_{x=1/2}
\]

(56)

where \( q_x \) is the heat flux in the horizontal direction. We also compute the maximum and minimum Nusselt number along the left plate.
Tables 3 and 4 show the data obtained on successive meshes with $u_{LB} = \Delta t/\Delta x = 0.01$ and $u_{LB} = 0.0058$ (i.e., $Ma = 0.01$), respectively. We studied four different Rayleigh numbers, ranging from $Ra = 1000$ to $Ra = 1000000$. For a comparison with existing results in the literature we fixed the Prandtl number at $Pr = 0.71$. The entries “/” indicate that no data was able to be obtained. For the $Ra = 1000$ case in Table 3, the inability to obtain data is believed to be the due to compressibility effects in the moment method, where we must calculate $\rho$ at the wall. The only other time we could not obtain data was when $Ra = 1000000$ on a very coarse $17 \times 17$ grid. The instability in this case is due to a negative value of the parameter $A$. Although some of the data obtained on the very coarse grids is clearly inaccurate, it is still interesting to note that that the algorithm was stable and converged to machine round-off with such a large grid spacing, $\Delta x$. A comparison of
Tables 3 and 4 show us that the scaled velocity $u_{LB}$, equivalently the Mach number $Ma$, has little effect on the accuracy of the model at larger $Ra$. The differences at smaller $Ra$ is due to the residual compressibility (we note that the largest $Ma$ number used here is larger than that in Wang et al. [31]). The magnitude of these differences rapidly decreases and we lower the Mach number further.

</table>

Table 3: Nusselt numbers for convection in a cavity. $Pr = 0.71$, $u_{LB} = 0.01$. '/' denotes no data could be obtained.
Table 4: Nusselt numbers for convection in a cavity with $Pr = 0.71$ and $u_{LB} = 0.0058$.

The data given in Tables 3 and 4 show the expected increase of the Nusselt numbers with Raleigh number. A similar trend is observed in Table 5, which gives the value of the streamfunction at the cavity midpoint and the maximum value of the streamfunction for different $Ra$ numbers. These are identical for $Ra = 1000$ and $Ra = 10000$ but differ at larger Rayleigh numbers, as is to be expected. The numerical predictions discussed above are seen to converge with second order accuracy. This observation is confirmed by Table 6, which shows the global $L_2$ error norm for the velocity, pressure, and temperature. The global $L_2$ error norm for velocity is defined to be
\[
\|\delta \mathbf{u}\|_2 = \frac{\sum_{i,j} \|u(x) - u^{REF}(x)\|_2}{\sum_{i,j} \|u^{REF}(x)\|_2}
\]  

(57)

where \( u^{REF} \) is the reference data obtained on the finest grid. The \( L_2 \) error norms for pressure and temperature were computed in a similar way. The strong (at least) second order convergence rate shown in Table 6 for all flow fields confirms the consistency and robustness of our model.

The flow fields at all studied Rayleigh numbers are plotted in Figure 3. The plots for the streamlines are coloured by the vertical component of velocity. Evidently, our lattice Boltzmann model is capturing the distinguishing flow patterns of natural convection in a cavity: at low Rayleigh numbers there is a dominant recirculating motion in the core region; and at higher \( Ra \) a prominent boundary layer develops along the wall. To assess the accuracy of the model we compare in Tables 7 and 8 our extrapolated results with benchmark data in the literature. An excellent agreement between the present and existing data sets is observed for the streamfunctions and Nusselt numbers at all values of \( Ra \) studied.

7. Convection in a partially heated cavity

For a final study we consider natural convection inside an air–filled square cavity, partially heated from below and cooled from the left. The geometry is as Figure 2 but the left wall is cold ($\theta(0, y) = 0$) and the right is perfectly insulated. The bottom wall is again adiabatic except in the region $1/2 - \epsilon/2 \leq x \leq 1/2 + \epsilon/2$, where $\theta(x, 0) = 1$ and $\epsilon = 0.2$. This flow is of relevance to the electronics industry and MEMS, where it is desirable to optimise the fluid circulation and cooling performance based on geometry in order the reduce the need for mechanical fans.
The flow fields are plotted in Figure 4. The background contours in the streamline plot are coloured by the horizontal component of the velocity. The flow has a large roll-cell with a primary vortex region near the centre of the cavity and smaller internal vorticies off-centre. Table 9 shows the computed Nusselt number \( Nu_c = \int_0^1 \partial_x \phi|_{x=0} dy \) along the cold wall and the maximum value of both components of velocity for different mesh sizes. For comparison we also show the results obtained by Cianfrini et al. on their finest mesh using a finite difference method. Once again, the lattice Boltzmann predictions are in good agreement with existing results. However, the difference between the two data sets is larger than in Section 6 and a few comments are in order. Firstly we should note that the percentage difference between our predictions on successive meshes is monotonically decreasing, whereas the grid sensitivity analysis in Cianfrini et al. [43] shows some non-monotonic behaviour. We would thus argue that our model is numerically robust to mesh refinements. Table 9 also shows that the maximum values of velocity converge with second order accuracy in space but the Nusselt number is converging with only first order. This is confirmed in Table 10 which gives
the relative $L_2$ error for the velocity, pressure, and temperature. One can see that the global velocity error is decreasing like $O(\Delta x^2)$, but the temperature like $O(\Delta x)$. We are of the opinion that this decrease in accuracy of $T$ is due to a lower order approximation of the temperature flux along the bottom wall, which is possibly enhanced by an insufficient initialisation procedure. This small but interesting anomaly will be addressed in our future research.

![Table 9: Average Nusselt number along the cold wall and maximum values for the velocity in a partially heated cavity. The table also shows the dependency of the results on the mesh, and a comparison with the finite–difference results of Cianfrini et al. on their finest grid. $Pr = 0.71$, $Ra = 1000000$ and $u_{LB} = 0.01$.](image)

The convergence of the flow fields is shown in Table 10.

8. Conclusion

Boundary conditions for the lattice Boltzmann equation are most commonly applied using the bounce-back method. Despite its simplicity, bounce-back introduces a spurious slip velocity of order $O(\Delta x^2)$ [32, 33]. To minimise this error without excessive mesh resolution, one must adjust the relaxation time of the third order moment according to the “magic parameter” [32]. If this relationship between the relaxation times for the second and third order moments is satisfied, the lattice Boltzmann method can accurately simulate flow phenomena, including natural convection [31]. However, the need to eliminate the numerical slip associated with bounce-back places a restriction on the collision operator. In particular, the value of the magic parameter $\Lambda = 3/16$ is not necessarily optimal in terms of numerical stability [34]. Furthermore, hydrodynamic boundary conditions more complicated than non-slip are not easily satisfied by bounce-back and its variants.

We have presented an application of moment-based boundary conditions for the lattice Boltzmann equation for natural convection. The moment method was originally proposed by Bennett [36] and may be viewed as an ex-
tension and generalisation of Noble’s method for hexagonal lattices [35]. Unlike all existing lattice Boltzmann boundary conditions, the moment method is formulated purely in terms of hydrodynamic variables at grid points. The constrained moments at the wall are solved in terms of the unknown (incoming) discrete velocity distribution functions. The moment method does not compromise the locality nor the order of accuracy of the lattice Boltzmann equation and allows us to evaluate flow variables precisely at grid points. There is no numerical slip error in the moment method.

The method has been applied to the two distribution functions for a thermal MRT lattice Boltzmann model. The ghost relaxation times have been chosen in accordance with numerical stability analysis [34] and not to satisfy the no-slip condition. We have evaluated the model for natural convection in square cavities and assessed its accuracy. Our results for the Nusselt numbers and the streamfunction are in excellent agreement with benchmark data for all tested Rayleigh numbers. The algorithm is numerically stable on coarse meshes and has been shown to converge with second order accuracy. As a first step towards solving industrially–relevant convection problems, we have also shown how easily the moment method can be applied to partially heated convection problems. Our numerical investigation has shown that the moment method can be a viable alternative to bounce–back for thermal flows in planar geometries, offering the possibility to incorporate more complicated boundary conditions into the lattice Boltzmann framework.
